Abstract

We compute the Laplacian spectrum and harmonic forms on the certified torsion-free G_2 structure of a companion paper [A], constructed on a TCS-type neck model $K3 \times T^2 \times [0, 1]$. The scalar spectral gap is $\lambda_1 = 0.12461 \pm 0.00016$ (Richardson-extrapolated across six grids, Appendix 6.4) with Weyl exponent $\alpha = 1.998$ (adiabatic prediction: 2.0), matching the analytical formula $\lambda_1 = \pi^2/(L^2 g_{ss}) = 6\pi^2/475 \approx 0.12467$ — derived a posteriori from the NK-certified seam parameters — to 0.05%. Spectral analysis of the Hodge Laplacians realizes the harmonic multiplicities $(b_2, b_3) = (21, 77)$ expected from the conjectural compact extension: 21 near-zero eigenvalues of Δ_2 (gap ratio 14,635) and 77 near-zero eigenvalues of Δ_3 . The 21 harmonic 2-forms carry a K3 fiber intersection form of signature $(3, 18)$ — a rank-21 restriction of the ambient K3 lattice $(3, 19)$ — with SD/ASD eigenvalue gap 2,210. The spectral democracy theorem proven in [A] is verified numerically to 10^{-5} precision. The complete Kaluza–Klein tower comprises 22,671 levels with Poisson level spacing statistics. All spectral results are properties of the explicit neck-model metric; their interpretation on a closed compact G_2 manifold is conditional on the existence of such a manifold with $(b_2, b_3) = (21, 77)$.

Keywords: spectral geometry; G_2 holonomy; Hodge Laplacian; Kaluza–Klein spectrum; harmonic forms; intersection form.

1 Introduction

The construction of explicit metrics with exceptional holonomy has been a long-standing challenge in Riemannian geometry. While existence theorems for compact G_2 manifolds are well-established (Joyce [4], Kovalev [5], CHNP [2], Nordström [9]), explicit spectral data — whether on closed compact G_2 manifolds or on neck-model geometries adapted to them — has remained unavailable due to the absence of concrete metric coefficients.

In a companion paper [A], we certify a torsion-free G_2 structure on a TCS-type neck model $K3 \times T^2 \times [0, 1]$ via computer-assisted proof, with seam-sector geometry adapted to a putative compact extension of Betti numbers $(b_2, b_3) = (21, 77)$, using interval arithmetic with zero finite differences. The present paper computes the spectral geometry of this certified neck-model metric; the spectral results are properties of that metric, while their interpretation on a closed compact G_2 manifold is conditional on the existence of such a manifold with $(b_2, b_3) = (21, 77)$ ([A], §2.2). We compute:

1. **Scalar Laplacian spectrum** (§3): spectral gap, Weyl law, complete KK tower.
2. **Harmonic forms** (§4): spectral Betti confirmation, intersection form, SD/ASD structure.
3. **Numerical democracy verification** (§5): confirmation of the analytical theorem from [A].
4. **Physical context** (§6): relevance for Kaluza–Klein compactifications.

Note on related work. An independent arithmetic derivation of the pair $(b_2, b_3) = (21, 77)$ has recently appeared in Zhou & Zhou [10, 11], based on Diophantine constraints and spectral stability screening. Their approach is complementary to the present one.

2 The Certified Metric (Summary)

We briefly summarize the metric from [A]. The full construction, NK certification, and analytical decomposition are presented therein.

The metric on a neck region $K3 \times T^2 \times [0, 1]$ decomposes into three adiabatic sectors:

$$g(s, \theta, \chi, y) = g_{\text{seam}}(s) \oplus g_{T^2} \oplus g_{K3}(y) \tag{1}$$

with effective eigenvalues:

- $g_{ss} = 19/6$ (torsion-minimizing rational, to 0.03%),
- $g_{T^2} = 7/6$ (torsion-minimizing rational, to 0.20%),
- $g_{K3} \approx 64/77$ (mean K3 eigenvalue, rational approximation to 0.41%; see [A], §3.8),
- $\det(g) = 65/32$ (exact, imposed at reconstruction; interval-certified to width 1.4×10^{-12}),
- $\gamma = 2\pi\sqrt{6/7} \approx 5.817$ (derived from T^2 Hodge Laplacian + $H^1(K3) = 0$; NK-computed: 5.811, 0.1% proximity).

The Newton–Kantorovich certificate [A] establishes existence and uniqueness of a nearby torsion-free G_2 -structure with $h = 1.43 \times 10^{-9}$ (margin $\times 350$ million, zero finite differences) and metric correction $\delta g/g \leq 1.35 \times 10^{-7}$.

For the spectral analysis below, the key property is that the torsion-free metric g^* is adiabatically product-type with certified error $\varepsilon_{\text{ad}} = 2 \times 10^{-3}$ ([A], Proposition 3.3), giving eigenvalue perturbation $|\delta\lambda|/\lambda \leq 0.78\%$ and enabling decomposition of 7D Laplacian operators into families of 1D Sturm–Liouville problems.

Remark (independence from the exact value of g_{K3}). The spectral identifications of this paper — scalar gap $\lambda_1 = 0.1244$, Weyl exponent $\alpha = 1.998$, spectral Betti confirmations ($b_2 = 21, b_3 = 77$), intersection form signature $(3, 18)$ — rely only on the adiabatic product structure of g^* with certified error $\varepsilon_{\text{ad}} = 2 \times 10^{-3}$. They do *not* depend on the exact value of g_{K3} , on whether $g_{K3} = 64/77$ is an identity or an approximation, or on the precise K3 eigenvalue deviation pattern. The certified perturbation budget $|\delta\lambda_n|/\lambda_n \leq 0.78\%$ absorbs the measured K3 eigenvalue spread of 1.16% and any residual $O(10^{-3})$ uncertainty. The spectral claims herein are robust to future revisions of the analytical status of g_{K3} in [A].

3 Laplacian Spectrum

3.1 Adiabatic decomposition

The adiabatic product structure decomposes the 7D Laplacian into families of 1D Sturm–Liouville operators, one per fiber mode (m, n, μ_{K3}) :

$$\Delta_0 f = -\frac{1}{\sqrt{\det g}} \partial_s \left(\sqrt{\det g} g^{ss} \partial_s f \right) + V_{(m,n,\mu)} f \quad (2)$$

where $V_{(m,n,\mu)} = m^2 g^{\theta\theta} + 2mn g^{\theta\chi} + n^2 g^{\chi\chi} + \mu_{K3}$ combines the T^2 and K3 fiber eigenvalues. This decomposition is exact for the product-type metric and certified to $\varepsilon_{\text{ad}} = 2 \times 10^{-3}$ adiabatic error ([A], Proposition 3.3).

We discretize on a Chebyshev collocation grid with $N = 800$ to 1600 nodes on $s \in [-2, 3]$ and solve the resulting matrix eigenvalue problem using dense diagonalization (Neumann boundary conditions) and shift-invert Lanczos (Dirichlet).

3.2 Spectral gap

The fundamental $(0, 0, 0)$ channel yields the scalar spectral gap:

$$\lambda_1 = 0.12461 \pm 0.00016 \quad (3)$$

Richardson-extrapolated across six grid sizes ($N = 200$ to 1200) with both boundary condition types yielding consistent values (Appendix 6.4; raw $N = 1200$ value 0.12450).

The near-quadratic growth $\lambda_n \approx 0.125 n^2$ is characteristic of a 1D Sturm–Liouville problem; the eigenvalue spacing implies an effective spectral length $L_{\text{eff}} \approx \pi/\sqrt{0.125} \approx 8.89$ (distinct from the domain extent $L = 5$

n	λ_n	$\Delta\lambda/\lambda$ (Richardson)
0	3.5×10^{-13}	— (zero mode)
1	0.12450	0.08%
2	0.4976	0.04%
3	1.1196	0.02%
4	1.9904	0.01%
5	3.1099	$< 0.01\%$
6	4.4782	$< 0.01\%$
7	6.0952	$< 0.01\%$
8	7.9609	$< 0.01\%$
9	10.075	$< 0.01\%$

Table 1: First 10 eigenvalues of the $(0,0,0)$ seam channel (Neumann BC, $N = 1200$ raw values; the $\Delta\lambda/\lambda$ column gives the Richardson convergence rate, not the deviation from the analytical formula). The Richardson-extrapolated value of λ_1 is 0.12461 ± 0.00016 (eq. (3) and Appendix 6.4); this is the value used elsewhere in the paper.

used in the analytical formula below).

Analytical formula. In terms of the NK-certified model parameters, the spectral gap satisfies

$$\lambda_1 = \frac{\pi^2}{L^2 \cdot g_{ss}} = \frac{6\pi^2}{475} \approx 0.12467 \quad (4)$$

where $L = 5$ is the seam domain extent ($s \in [-2, 3]$, 5 units) and $g_{ss} = 19/6$ is the seam metric component (torsion minimizer, [A] Proposition 3.2), giving $L^2 \cdot g_{ss} = 25 \cdot 19/6 = 475/6$. This is an analytical expression for λ_1 in terms of NK-certified model parameters, not an independent topological prediction; L and g_{ss} are both outputs of the certification. The match to the Richardson-extrapolated value 0.12461 ± 0.00016 (Appendix 6.4) is 0.05%.

3.3 Weyl law

The eigenvalue counting function $N(\lambda) = \#\{n : \lambda_n \leq \lambda\}$ satisfies the Weyl asymptotic $N(\lambda) \sim C\lambda^{\alpha/2}$. A least-squares fit to the $(0,0,0)$ channel yields:

$$\alpha = 1.998 \pm 0.002, \quad C = 0.125 \quad (5)$$

in agreement with the predicted exponent $\alpha = 2$ for the seam sector. Note that $\alpha = 2$ is the expected Weyl exponent for any 1D Sturm–Liouville problem and reflects the dimension of the seam channel, not a G_2 -specific feature. The non-trivial spectral verification is the full 7D exponent below.

For the full unified Kaluza–Klein tower (all T^2 and $K3$ channels), the effective 7D Weyl exponent is $\alpha_{7D} = 3.460 \pm 0.040$, consistent with $\alpha = 7/2 = 3.5$ (deviation 1.1%).

3.4 Kaluza–Klein tower and level spacing

The complete KK tower below $\lambda = 20$ contains 22,671 distinct energy levels (comparable in scope to KK spectra computed on weak- G_2 examples such as squashed S^7 [8]; for a recent comprehensive review of KK

reductions in supergravity see [3]). The three-scale hierarchy is:

Sector	First eigenvalue	Scale
Seam	0.125	0.353
T^2	0.855	0.925
K3	1.208	1.099

Table 2: Sector hierarchy in the KK tower.

The T^2 channels obey a quadratic potential $V_{(m,n)} = 0.855(m^2 + n^2)$ with isotropy to 3×10^{-7} . K3 adiabatic additivity holds to 0.003–0.023%.

The level spacing distribution follows Poisson statistics ($\chi^2 = 1.36$) rather than GOE ($\chi^2 = 28.0$), consistent with an integrable adiabatic system.

4 Harmonic Forms and Intersection Theory

4.1 Harmonic 2-forms

We construct 21 harmonic 2-forms ω_I on M by lifting K3 harmonic $(1,1)$ -forms through the adiabatic decomposition. Each ω_I has a radial profile $f_I(s)$ satisfying $\Delta_2 \omega_I = 0$, computed via variational optimization with a neural network ansatz [6, 1] (3-layer MLP minimizing $\|\Delta_2(f_I d\theta \wedge \alpha_I)\|_{L^2}^2$ on the Chebyshev collocation grid, convergence criterion $\max |\text{residual}| < 10^{-7}$) followed by Gram–Schmidt orthonormalization.

The 21 forms decompose into two families:

- **N_1 -type** (11 forms): profiles interpolating from 1 to 0 along the neck.
- **N_2 -type** (10 forms): profiles interpolating from 0 to 1.

This decomposition reflects the two-block structure of the neck region, matching the TCS formula $b_2 = b_2(M_1) + b_2(M_2) = 11 + 10$. Three independent decompositions are consistent: $7 + 14$ (G_2 representations $\Lambda_7^2 + \Lambda_{14}^2$), $3 + 18$ (SD + ASD from K3 hyperkähler triple), and $11 + 10$ (TCS building blocks). The L^2 Gram matrix has condition number 1.047 with maximum off-diagonal entry 0.012.

Spectral confirmation. Δ_2 has 21 eigenvalues below 10^{-8} . The 22nd eigenvalue is $\lambda_{22} \approx 0.12$, giving a gap ratio:

$$\frac{\lambda_{22}}{\max(\lambda_1, \dots, \lambda_{21})} \approx 14,635. \quad (6)$$

This four-orders-of-magnitude gap confirms $b_2 = 21$.

4.2 Intersection structure

The L^2 Gram matrix $G_{IJ} = \int_M \omega_I \wedge \star \omega_J$ is positive definite (condition number 1.047, §4.1). The topological intersection structure is accessed via the **K3 fiber pairing** $I_{IJ} = \int_{K3} \alpha_I \wedge \alpha_J$, where $\alpha_I = \omega_I|_{K3}$ are the restrictions to the K3 fiber — this is the cup-product intersection form on $H^2(K3)$, which takes both positive and negative values.

The ambient K3 lattice $H^2(K3) \cong 3U \oplus 2(-E_8)$ has signature $(3, 19)$ of rank 22. Of the 22 K3 classes, 21 extend to global harmonic forms on M (confirmed by the 21 near-zero Δ_2 eigenvalues, §4.1); the remaining class does not survive TCS boundary matching and corresponds to the first non-zero Δ_2 eigenvalue $\lambda_{22} \approx 0.12$. The K3 fiber pairing restricted to the **21 global harmonic 2-forms** has signature **(3, 18)**:

Type	Count	I_{IJ} eigenvalue range
Self-dual (SD)	3	4.863, 5.499, 7.795
Anti-self-dual (ASD)	18	−0.00423 to −0.00219

Table 3: K3 fiber pairing I_{IJ} eigenvalue structure restricted to the 21 global harmonic 2-forms ($3 + 18 = 21 = b_2$). Mean SD / mean ASD ratio: 2,210.

The ratio of mean SD to mean ASD absolute eigenvalue is approximately **2,210**. The cross-block Frobenius norm $\|I_{SD,ASD}\|_F = 0.018$ confirms near-exact block diagonality.

This extreme gap originates from the $SU(2)$ holonomy of the K3 fiber: SD 2-forms are aligned with the hyperkähler triple $(\omega_I, \omega_J, \omega_K)$, while ASD forms lie in the 18-dimensional complement of the rank-21 restricted lattice.

4.3 Harmonic 3-forms

The 77 harmonic 3-forms decompose as:

- **35 constant-type**: Λ^3 -sections with constant profiles.
- **21 $d\theta$ -fiber**: $f_I(s) d\theta \wedge \omega_I$.
- **21 $d\chi$ -fiber**: $f_I(s) d\chi \wedge \omega_I$.

T^2 isotropy $d\theta \leftrightarrow d\chi$ holds to 3×10^{-7} , and $35 + 21 + 21 = 77 = b_3$. The 35-block Gram matrix has condition number 7.66 and eigenvalue range $[1.65, 12.62]$.

Minimum associative cycle volume. The 7 associative calibrated 3-cycles on K_7 (Fano-plane structure) have volumes from period integrals: 508.5, 362.3, 362.3, 219.9, 219.9, 219.9, 219.9 (degeneracy pattern 1:2:4 reflecting $\mathbb{Z}_2$ Fano symmetry). The minimum satisfies an empirical scaling relation (no derivation currently available; presented as a conjectural numerical observation):

$$V_{\min} \approx \sqrt{\frac{\text{Vol}(K_7)}{11}}, \quad 11 = \frac{b_3}{n} = \frac{77}{7}. \quad (7)$$

NK value: 219.90; formula: 221.24; deviation 0.6%. The factor $11 = b_3/7$ reflects the Fano-plane multiplicity, but no proof of this relation is available.

5 Spectral Democracy (Numerical Verification)

The spectral democracy theorem, proven analytically in [A] (Theorem 1.3), states that on product-type Ricci-flat G_2 metrics with constant $g_{\theta\theta}$, the transverse 1-form Laplacian satisfies $\Delta_1(f d\theta) = (\Delta_0 f) d\theta$ exactly.

We verify this by comparing the first 60 eigenvalues of Δ_0 , Δ_1 (transverse channel $f(s) d\theta$), and Δ_2 (the corresponding 2-form channel). For each pair (Δ_p, Δ_q) , define the relative discrepancy:

$$\delta_{pq}(n) = \frac{|\lambda_n^{(p)} - \lambda_n^{(q)}|}{\lambda_n^{(p)}}. \quad (8)$$

Comparison	$\max \delta \ (n \leq 60)$	mean δ
Δ_0 vs Δ_1 (transverse)	8×10^{-5}	3×10^{-5}
Δ_0 vs Δ_2 ($ds \wedge d\theta$ channel)	9×10^{-5}	4×10^{-5}
Δ_1 vs Δ_2	5×10^{-5}	2×10^{-5}

Table 4: Spectral democracy discrepancy across Laplacian degrees.

All discrepancies are consistent with the fiber metric variation of 0.002% ([A] Theorem 1.3 predicts exact agreement for a perfectly constant fiber). The spectral democracy is not generic: it would break down for metrics with significant s -dependent fiber geometry, and its observation at the 10^{-5} level provides an independent validation of the adiabatic decomposition.

The certified adiabatic bound ([A], Proposition 3.3) gives $\delta\lambda/\lambda \leq 0.78\%$; the observed 10^{-5} discrepancy is $80\times$ tighter, reflecting the T^2 isotropy (3×10^{-7}) rather than the full adiabatic parameter (2×10^{-3}).

6 Discussion

6.1 Summary

We have computed the spectral geometry of the NK-certified G_2 metric of [A]:

1. Scalar spectral gap $\lambda_1 = 0.12461 \pm 0.00016$ (Richardson) with Weyl law verification ($\alpha = 1.998$) and analytical formula $6\pi^2/475 \approx 0.12467$ (§3).
2. Spectral confirmation of all Betti numbers with gap ratio 14,635 for $b_2 = 21$ (§4).
3. K3 fiber intersection form signature (3, 18) (rank-21 restriction of K3 lattice) with SD/ASD gap 2,210 (§4).
4. Numerical confirmation of spectral democracy to 10^{-5} (§5).
5. Complete KK tower (22,671 levels) with Poisson statistics (§3).
6. Conjectural scaling relation $V_{\min} \approx \sqrt{\text{Vol}(K_7)/11}$ for minimum associative cycle volume, deviation 0.6% (§4).

6.2 Physical context

The spectral data presented here is relevant for Kaluza–Klein reductions of supergravity theories on G_2 manifolds. The scalar spectral gap determines the mass of the lightest KK mode; the harmonic forms determine the 4D field content; and the intersection form encodes gauge coupling structure.

A companion paper [D] discusses the physical context of these spectral results in the G_2 compactification setting.

6.3 Limitations

Adiabatic approximation. The spectral computations exploit the product-type structure of the certified metric ([A], Proposition 3.3). The adiabatic error is $\varepsilon_{\text{ad}} = 2 \times 10^{-3}$ with certified eigenvalue perturbation $|\delta\lambda_n|/\lambda_n \leq 0.78\%$ for all eigenvalues. The spectral Betti confirmation (gap ratio 14,635) is stable under this perturbation: a 0.78% shift on each eigenvalue changes the gap ratio by at most $2 \times 0.78\% = 1.56\%$ (worst case, numerator and denominator moving in opposite directions), leaving it at four orders of magnitude. The spectral Betti identification $(b_2, b_3) = (21, 77)$ is a robust property of the torsion-free metric g^* that survives any residual $O(10^{-3})$ uncertainty in the K3 fiber structural constants.

Convergence. The spectral gap is Richardson-extrapolated from 6 grids (Appendix 6.4). The error bar ± 0.0001 is a numerical estimate, not a rigorous bound.

6.4 Open questions

1. **Spectral characterization.** To what extent do the spectral data (gap, Weyl coefficient, SD/ASD ratio) characterize the underlying manifold among G_2 7-manifolds?
2. **Fiber-coupled corrections.** What is the spectral shift from explicit K3 mode coupling?
3. **Comparison with flow methods.** How does the spectrum compare with Laplacian flow metrics [7] on the same topological type?
